(Received 28 May 2012; final version received 24 October 2012)

The hepatic blood circulation is complex, particularly at the microcirculatory level. Previously, 2D liver lobule models using porous media and a 3D model using real sinusoidal geometries have been developed. We extended these models to investigate the role of vascular septa (VS) and anisotropic permeability. The lobule was modelled as a hexagonal prism (with or without VS) and the tissue was treated as a porous medium (isotropic or anisotropic permeability). Models were solved using computational fluid dynamics. VS inclusion resulted in more spatially homogeneous perfusion. Anisotropic permeability resulted in a larger axial velocity component than isotropic permeability. A parameter study revealed that results are most sensitive to the lobule size and radial pressure drop. Our model provides insight into hepatic microhaemodynamics, and suggests that inclusion of VS in the model leads to perfusion patterns that are likely to reflect physiological reality. The model has potential for applications to unphysiological and pathological conditions.

### Nomenclature

2D:	two-dimensional
3D:	three-dimensional
$K$ :	permeability tensor
$p$ (Pa):	pressure
$Q$ (m <sup>3</sup> /s):	flow
$R$ (mmHg min/ml):	vascular resistance
$V$ (m <sup>3</sup> ):	volume
$k$ (m <sup>2</sup> ):	permeability coefficient
$\vec{v}$ :	velocity vector
$\varepsilon$ :	porosity
$\mu$ (Pa s):	dynamic viscosity
$\rho$ (kg/m <sup>3</sup> ):	density

### 1. Introduction

The perfusion of the liver is complex and distinct from that of other organs, mainly due to its dual blood supply from both the hepatic artery and the portal vein (Burt et al. 2007; Marieb and Hoehn 2008; Debbaut et al. 2011; Monbaliu et al. 2012). In particular, the microcirculation on the scale of the liver lobules and sinusoids displays complicated

haemodynamics (Greenway and Stark 1971; Matsumoto et al. 1979; Matsumoto and Kawakami 1982; Ekataksin and Wake 1991; Teutsch et al. 1999; Burt et al. 2007; Marieb and Hoehn 2008).

In the literature, microperfusion of the liver is often schematically represented in terms of classical lobules, each having the shape of a hexagonal prism (Figure 1; Burt et al. 2007; Marieb and Hoehn 2008). Liver lobules are assumed to be configured in a tessellating pattern, similar to the organisation of hexagonal wax cells in the honeycombs of bees. Blood enters a lobule via the portal tracts (PTs), located at the corners. Each PT contains a hepatic arteriole (supplying the liver with oxygenated blood), a portal venule (providing nutrient-rich blood from the intestines) and a bile ductule. The latter drains the bile produced in the lobule in the opposite direction from the blood flow in the PT. A fraction of the blood from the PT enters the vascular septa (VS), which are the vascular surfaces between neighbouring lobules, bordered at opposite edges by two PTs (Figure 1). As such, the VS foresee the blood supply of the tissue between PTs by a number of microvessels branching off the PTs. Blood flows from the PTs and VS into the interconnected network of tortuous sinusoids, which are the hepatic-specific capillaries and are lined by a fenestrated

Figure 1. Schematic representation of the hepatic microcirculation. (a) Liver lobule with the shape of a hexagonal prism and its vascular network and (b) spatial organisation of the liver lobules. A liver acinus is indicated by the white dotted line.

endothelial cell layer. Blood solutes can flow through the fenestrations into the space of Disse, which is the space between the endothelial cells and the hepatocytes. Here, the metabolic exchange (e.g. oxygen or nutrient uptake) takes place with the neighbouring hepatocytes. The blood is further drained from the sinusoids into the central vein (CV), and from there into the hepatic veins and vena cava inferior (Burt et al. 2007; Marieb and Hoehn 2008). Due to the liver's microvascular organisation and its metabolic functions, liver lobules are characterised by metabolic zonation (Zou et al. 1998; Burt et al. 2007). For example, the cell zone closest to the PTs will receive blood that is rich in nutrients and oxygen, while the zone close to the CV receives blood that is poorer in nutrients and oxygen. Although the liver lobule is the most frequently used functional liver unit, a number of other units have been proposed in the past, such as the hepatic acinus (Rappaport et al. 1954; dotted line in Figure 1(b)) and the primary lobule (Matsumoto et al. 1979; Matsumoto and Kawakami 1982). Nevertheless, the actual real 3D structure of the liver microcirculation seems to be more complicated, as was illustrated in one of our previous papers (Debbaut et al. 2012), on the basis of a high-resolution 3D micro-CT dataset of the human liver microcirculation, and liver lobules are not always perfect prisms. Additionally, variations are frequently observed in the number of PTs per lobule (polyhedral lobules with four, five or seven corners instead of six).

Until now, our knowledge of the liver microcirculation is mainly based on schematic concepts, and its haemodynamic behaviour is still not fully understood. Especially in the case of abnormal liver conditions, the liver microcirculation plays a crucial role: when impaired or damaged (for instance, due to disease), this can result in a loss of liver function due to the tight coupling between liver microperfusion and its metabolic function. Consequently, it is necessary to gain more insight into liver microvascular haemodynamics to also have a deeper understanding of its function. Previously, numerical models have been used successfully to better understand

the microcirculation. These models (or modelling techniques) might be helpful to understand microhaemodynamics in a healthy liver as well as in liver pathology. Knowing that the microcirculation operates within relatively narrow ranges of haemodynamic conditions, microcirculation alterations might lead to biomechanical stressors (high shear stresses, high wall stresses). As such, these numerical models are applicable to investigate transplant-related phenomena (for which the preservation of the hepatic microcirculation is crucial for the viability of the liver graft (Monbaliu et al. 2007; Monbaliu and Brassil 2010)), pathology-related microvascular alterations (e.g. in the case of fibrosis, cirrhosis (Vanheule et al. 2008; Chen et al. 2009), hepatocellular carcinoma (Maksan et al. 2003), steatosis (Rosenstengel et al. 2011), portal hypertension (Yagi et al. 2005; Fondevila et al. 2010)), as well as surgery-induced effects (e.g. small-for-size liver syndrome after partial hepatectomy (Tanaka and Ogura 2004; Glanemann et al. 2005; Ikegami et al. 2008)). For example, cirrhosis is known to alter and deteriorate the liver's microvessel structure, leading to higher vascular resistances, which could be modelled by changing the structure-related parameters such as the permeability. Next to these applications, reduced-order versions of these models may also be implemented in larger scale models (e.g. Debbaut et al. 2011) to capture the total liver haemodynamics, incorporating the macro- as well as the meso- and microcirculation and the interaction of the liver with other organs in whole system models.

However, only a few models on the topic of liver microhaemodynamics have been published, which might be due to the complexity of the liver microcirculation and the difficulties associated with the acquisition of the required anatomical and functional data at sufficient resolution. A few studies focused on modelling the lobule haemodynamics based on porous medium approaches, in which the sinusoids are represented as pores imbedded in a parenchymal matrix. In one such study, Ricken et al. (2010) developed a 2D biphasic model of the blood flow in a longitudinal cross-section of the liver lobules using a

permeability that is isotropic over the cross-section. Bonfiglio et al. (2010) studied the flow patterns in a 2D hexagonal cross-section in a porous lobule model, assuming both isotropic permeability and 2D anisotropic permeability (radial vs. circumferential). Both these models neglected the existence of VS (Bonfiglio et al. 2010; Ricken et al. 2010), leading to predictions of poor perfusion of the regions midway between neighbouring PTs in the paper of Bonfiglio et al. (2010). Given the need to perfuse every hepatocyte well, this is unlikely to occur *in vivo*. Consequently, Siggers et al. (2010) used a 2D symmetric triangular porous medium model (representing one-sixth of a hexagonal cross-section of a lobule), which they solved analytically to investigate the effect of VS. The PT inflows, VS inflows and central outflows were approximated as point sources, line sources and point sinks, respectively.

Although the porous medium models described above are useful to capture the overall haemodynamics, they are based on a number of key assumptions. The flow is assumed to be planar (2D), although it is known that the real liver microcirculation has a complex 3D structure (Debbaut et al. 2012). In all but one section of the paper by Bonfiglio et al. (2010), the permeability is assumed to be isotropic. Furthermore, VS were either neglected (Bonfiglio et al. 2010; Ricken et al. 2010) or modelled as a line source, implying a constant inflow into the sinusoids along the length of the VS (Siggers et al. 2010). However, in reality, the inflow from the VS is likely to be smaller further away from the PTs (due to a lower pressure within the VS there). As these assumptions were not validated before, 3D models may be helpful to clarify

this. Rani et al. (2006) previously developed a finite volume blood flow model in a 3D geometry, incorporating a terminal hepatic arteriole, portal venule and CV, as well as two fenestrated sinusoids, using non-Newtonian blood properties. Though the modelling approach was sophisticated, an idealised 3D geometry was used to locally represent the blood flow from the PT, passing through two sinusoids into the CV. More complex tortuous and interconnected sinusoids as well as the VS were not taken into account here, while these are relevant for the haemodynamics at this level. In recent work, we developed a 3D numerical model of the liver terminal circulation based on high-resolution micro-CT data (Debbaut et al. 2012). We demonstrated that the 3D permeability tensor of a sinusoidal network displays significant anisotropy, which is in contrast with the isotropic permeability conditions assumed in the 2D porous models mentioned above (Bonfiglio et al. 2010; Ricken et al. 2010; Siggers et al. 2010). Working in a cylindrical coordinate system with the  $z$ -axis along the CV of a lobule (Figure 2), we found the permeability tensor to be approximately diagonal with an axial component roughly two times that of the radial and azimuthal components, which were themselves approximately equal.

Combining the strengths of the previous models and extending them could lead to a more accurate model and a better understanding of the hepatic microhaemodynamics. Therefore, the aim of this study was to develop a 3D porous medium model of the perfusion of a liver lobule, accounting for anisotropy in the permeability of the sinusoidal network and incorporating the VS as a separate

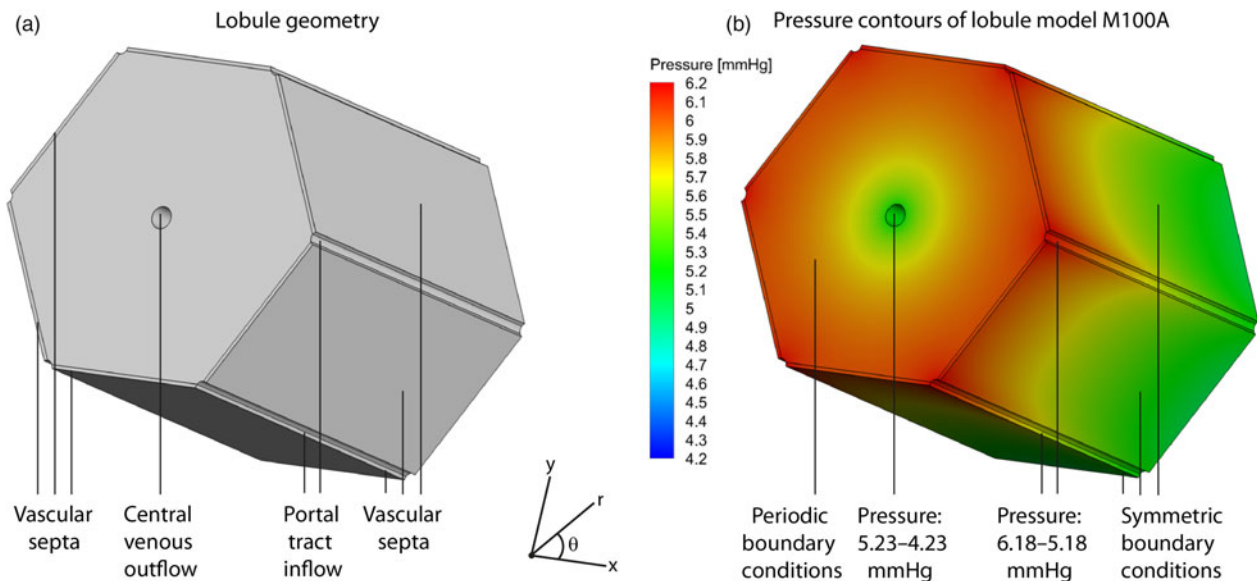

Figure 2. (a) Simulation geometry of a liver lobule and (b) pressure contours (in mmHg) obtained in model M100A. The  $z$ -axis of the cylindrical coordinate system is located along the longitudinal axis of the lobule and its origin is at the centre of the simulation geometry.

volume zone within the model. In addition, we carried out a parameter sensitivity analysis of the newly proposed model.

## 2. Materials and methods

### 2.1 Simulation geometry and mesh generation

A geometry, representing a liver lobule with VS, was studied using a cylindrical coordinate system  $(r, \theta, z)$ , with its  $z$ -axis along the CV and its origin at the centre of the simulation geometry (Figure 2(a)).

The lobule geometry (Figure 2(a)) was assumed to be a hexagonal prism, with cross-section defined by a circumscribing cylinder of diameter 1 mm (Burt et al. 2007; Mareels 2008), resulting in a hexagonal edge length of 0.5 mm. Lobules are reported to have lengths of up to several millimetres (Mareels 2008), and in this study, we used a length of 1 mm as a representative value. Reported measurements of the diameter of the CV and portal venule (corresponding to the major PT inflow) vary substantially in the literature (Nakata et al. 1960; Maass-Moreno and Rothe 1997; Teutsch et al. 1999; Teutsch 2005; Burt et al. 2007), and in our model, we chose representative values. As such, the CV was modelled as a cylinder of diameter 60  $\mu\text{m}$  parallel to the  $z$ -axis and the PTs along the six parallel edges as cylinders, each having a diameter of 40  $\mu\text{m}$ . VS zones were defined as the outermost 10  $\mu\text{m}$  depth on the six faces of the prism that delineate the borders with the neighbouring lobules (Figure 2(a)).

The simulation geometry was meshed with Gambit<sup>TM</sup> (Ansys, Canonsburg, PA, USA). A mesh sensitivity study was carried out by creating four meshes using the Cooper scheme, with the linked surface meshes of the top and bottom plane of the geometry as sources, and by applying an interval size of 24, 12, 6 and 5  $\mu\text{m}$ , resulting in  $4.6 \times 10^4$ ,  $3.8 \times 10^5$ ,  $3.1 \times 10^6$  and  $5.1 \times 10^6$  hexahedral volume elements, respectively. The mesh sensitivity analysis showed approximately constant results for models having  $3.1 \times 10^6$  or more elements. Consequently, the mesh with a 6  $\mu\text{m}$  interval size corresponding to  $3.1 \times 10^6$  elements was used.

### 2.2 Cell zone conditions and fluid properties

The volume of the lobule, representing the sinusoids, was characterised as a porous medium, with fluid flow given by Darcy's law:

$$\vec{v}_{\text{porous}} = -\frac{1}{\mu} K \nabla p, \quad (1)$$

where  $p$  (Pa) is the sinusoidal blood pressure,  $\mu$  (Pa s) is the dynamic viscosity of blood,  $K$  ( $\text{m}^2$ ) is the second-order permeability tensor and  $\vec{v}_{\text{porous}}$  (m/s) is the Darcy velocity

(Liakopoulos 1965). The permeability tensor  $K$  [consisting of permeability coefficients  $k$  ( $\text{m}^2$ ); Equation (2)] is represented by a diagonal matrix in the cylindrical coordinate system  $(r, \theta, z)$ :

$$K = \begin{bmatrix} k_{rr} & k_{r\theta} & k_{rz} \\ k_{\theta r} & k_{\theta\theta} & k_{\theta z} \\ k_{zr} & k_{z\theta} & k_{zz} \end{bmatrix} = \begin{bmatrix} k_{rr} & 0 & 0 \\ 0 & k_{\theta\theta} & 0 \\ 0 & 0 & k_{zz} \end{bmatrix}. \quad (2)$$

In this study, two different permeability tensors were used: an isotropic tensor and an anisotropic tensor. The anisotropic tensor was defined by the permeability coefficients found in Debbaut et al. (2012), giving  $k_{zz} = 3.64 \times 10^{-14} \text{ m}^2$ ,  $k_{rr} = 1.56 \times 10^{-14} \text{ m}^2$  and  $k_{\theta\theta} = 1.75 \times 10^{-14} \text{ m}^2$ . Isotropic permeability conditions were defined by assuming that the isotropic permeability is equal to the anisotropic radial permeability coefficient,  $k_{rr} = k_{\theta\theta} = k_{zz} = 1.56 \times 10^{-14} \text{ m}^2$ . This choice was based on the observation that the radial permeability coefficient has the biggest impact on the resulting volume flow rate at the lobule outflow (CV).

The porosity of the lobule,  $\varepsilon$ , equals the fraction of the volume occupied by the blood ( $V_{\text{sinusoids}}$ ) divided by the total volume  $V_{\text{total}}$  (Equation (3)), and we fixed its value at 0.143, as found in Debbaut et al. (2012). It also equals the ratio of the magnitude of the Darcy velocity (the volume-averaged flux per unit area;  $\vec{v}_{\text{porous}}$  (m/s)) to the magnitude of the cross-sectionally averaged physical velocity in the sinusoids ( $\vec{v}_{\text{physical}}$  (m/s)):

$$\varepsilon = \frac{V_{\text{sinusoids}}}{V_{\text{total}}} = \frac{\|\vec{v}_{\text{porous}}\|}{\|\vec{v}_{\text{physical}}\|}. \quad (3)$$

In the following, all reported velocities are Darcy velocities and we denote  $\vec{v}_{\text{porous}}$  simply by  $\vec{v}$ . In order to estimate the typical physical velocities within the sinusoids, the Darcy velocity should thus be divided by the porosity  $\varepsilon$  (Equation (3)).

For the model without VS, the VS zones were defined using the same permeability coefficients as for the lobule zone of the sinusoids. In the case of models with VS, VS were treated as porous media with a higher circumferential permeability due to the circumferential orientation of the vessels within the VS. As such, we used in the VS the lobular value of  $k_{\theta\theta}$  multiplied by a factor of either 10 or 100, but keeping the values of the radial and longitudinal coefficients,  $k_{rr}$  and  $k_{zz}$ , the same as their values in the sinusoids. Note that, ideally, we would have altered the component of the permeability tensor in the exact direction of the VS (rather than  $k_{\theta\theta}$  in the circumferential direction, which is approximately in the same direction), but in this paper, we considered this slightly simpler case.

In total, six cases were simulated to investigate the influence of including VS and the usage of (an)isotropy.

We denote these models as M0I, M0A, M10I, M10A, M100I and M100A, where '0' refers to no VS, '10' to VS with  $k_{\theta\theta}$  10 times that in the lobule interior and '100' to VS with  $k_{\theta\theta}$  100 times that in the lobule interior, 'I' refers to isotropic permeability and 'A' to anisotropic permeability (Table 1). Blood was assumed to be an incompressible Newtonian fluid, with a dynamic viscosity of 3.5 mPa s (van der Plaats et al. 2004).

### 2.3 Boundary conditions and computational fluid dynamics

For all models, the top and the bottom hexagonal planes were characterised by a translational periodic boundary condition (Figure 2(b)), and we assumed 1 mmHg/mm to be the  $z$ -component of the pressure gradient. The pressure was defined to drop from 6.18 to 5.18 mmHg along the PT inflow and from 5.23 to 4.23 mmHg along the CV outflow (corresponding to mean pressures of 5.68 mmHg at the PT and 4.73 mmHg at the CV, as found in Maass-Moreno and Rothe (1997)). At the planes of interface between the lobule and VS, continuity of pressure and flux was applied. Since we assumed a repeating honeycomb pattern (Figure 1(b)), we used symmetry boundary conditions at the surfaces delineating the lobule borders.

The steady computational fluid dynamic models were solved using Fluent<sup>TM</sup> (Ansys). Tecplot<sup>TM</sup> (Tecplot, Inc., Bellevue, WA, USA) was used to process, calculate and visualise the haemodynamic parameters of interest.

### 2.4 Parameter sensitivity study

Since some assumptions were made concerning the boundary conditions and simulation geometry, with some degree of variability in values reported in the literature, we carried out a parameter sensitivity analysis of the model. The M100A model was used as the baseline model to perform parameter variations of the pressure boundary conditions as well as geometry-related parameters (see also Table 1).

As such, the longitudinal pressure gradient was changed from the default value of 1 to 0 mmHg/mm (M100A\_1), 0.5 mmHg/mm (M100A\_2) and 2 mmHg/mm (M100A\_3). The pressure drop between the PTs and CV was changed by increasing the default PT pressure, defined to drop from 6.18 to 5.18 mmHg along the PT inflow, by 0.5 mmHg (M100A\_4) and 1 mmHg (M100A\_5).

The thickness of the VS was changed to 5  $\mu$ m (M100A\_6) instead of 10  $\mu$ m, and the PT (M100A\_7) and CV diameters (M100A\_8) were increased by 50% of their original value. Additionally, the effect of the lobule circumferential diameter was investigated by scaling down the lobule. Note that, if we would consider a scale model in which we change all length scales (lobule

circumferential diameter, and the radii of the CV and PTs) in the same way, the flux would remain unchanged, as the velocity scale is inversely proportional to the length scale. Consequently, we considered a lobule circumferential diameter of 0.5 mm instead of 1 mm, but kept the radii of the PT and CV the same (M100A\_9). A summary of all simulated cases and the corresponding parameters is shown in Table 1.

## 3. Results

We first compare the haemodynamics of the models with and without VS (Section 3.1), followed by a comparison of the isotropic and anisotropic permeability cases (Section 3.2). The results of the parameter sensitivity analysis are reported in Section 3.3.

### 3.1 Comparison of the models with and without VS

Since the impact of VS on the results for the isotropic and anisotropic models is qualitatively similar (Figures 3–7), we describe here only the results for the anisotropic models in detail.

#### 3.1.1 Flow in the hexagonal cross-sectional plane in the middle of the lobule ( $z = 0$ )

In model M0A, over the hexagonal cross-section  $z = 0$ , the pressure drops from 5.68 mmHg at the PTs to 5.40 mmHg at the points midway between neighbouring PTs to 4.73 mmHg at the CV (Figures 3(a) and 4(b)). The projection of the velocity into the cross-section,  $\|\vec{v}_{r\theta}\|$ , has a relatively high magnitude at the entry from the PTs (Figure 3(b)). From there, the blood flows to the CV, either directly, or first towards the regions midway between neighbouring PTs and then towards the CV. Along each pathway, the cross-sectional velocity decreases away from the PT, reaching a streamline-specific minimum (with the lowest value being a zero velocity, which is attained at the stagnation points at the outer lobule borders midway between neighbouring PTs; Figure 3(c)) before rising to its highest value at the CV outlet (Figure 3(d)).

As can be seen in Figure 4(d),(f), the model demonstrates different haemodynamics when VS is present. The pressure drop from the PT to the VS is smaller in M10A and M100A than in the case without VS (Figure 3(a)), and the pressure drop from the centre of the VS to the CV is larger. There are two flow pathways: those pathways on which fluid enters the sinusoids directly from the PTs and those on which fluid travels through the VS before entering the sinusoids. Within the VS, the flow is predominantly circumferential, and the cross-sectional velocities at the PT–VS interface are high. At the CV outflow, the velocities are approximately spatially uniform

Table 1. Overview of all simulations with the corresponding VS and permeability conditions, as well as the longitudinal pressure gradient, the lobule circumferential diameter, the pressure drop between the PTs and CV, the VS thickness and the PT and CV diameters.

Model	VS conditions ( $k_{\theta\theta}$ scaling factor)	Permeability conditions	Pressure gradient (z) (mmHg/mm)	Lobule diameter (mm)	PT–CV pressure difference (mmHg)	VS thickness ( $\mu\text{m}$ )	PT diameter ( $\mu\text{m}$ )	CV diameter ( $\mu\text{m}$ )

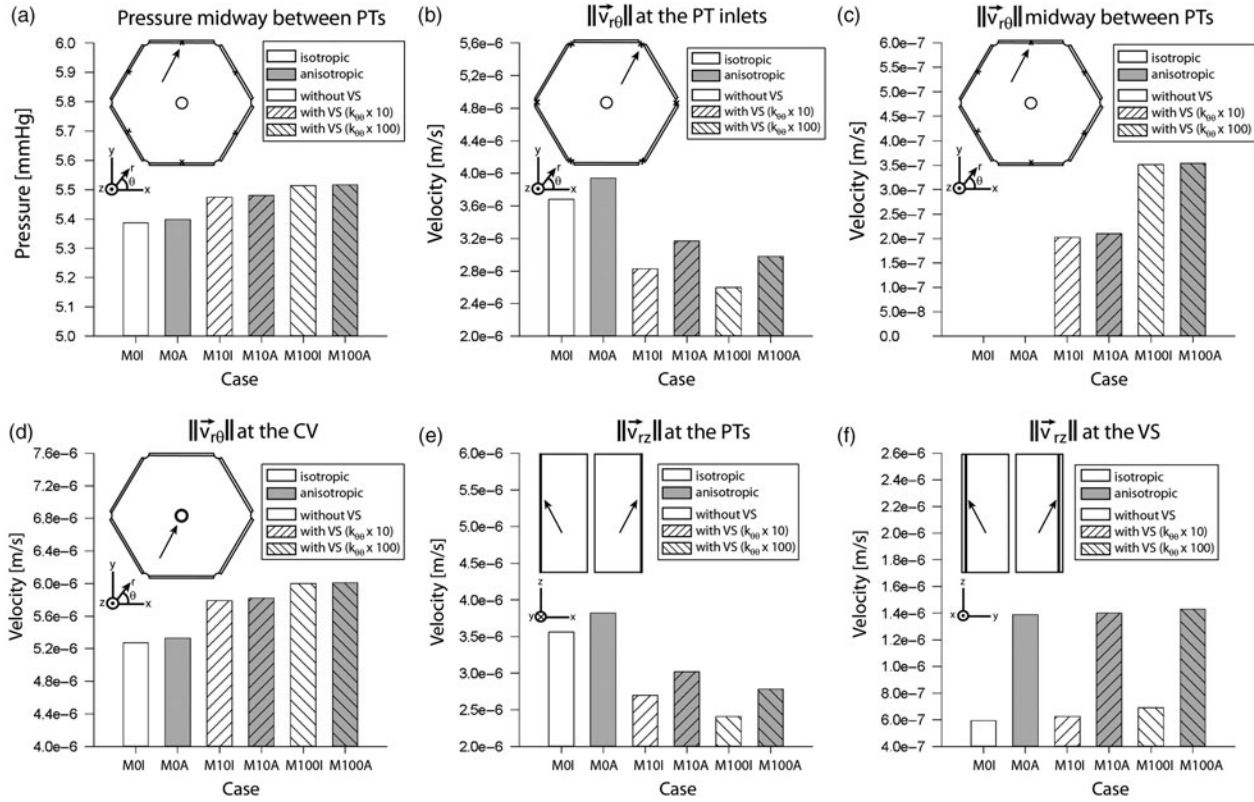

Figure 3. Comparison of the pressures and velocities at particular locations in the lobule for the models M0I, M0A, M10I, M10A, M100I and M100A: (a) pressure at the points midway between neighbouring PTs; (b–d) magnitudes of the cross-sectional projection of the velocity ( $\|\vec{v}_{r0}\|$ ): (b) at PT inlets (mean value over the PT inlet), (c) at the midpoints of the border lines of the sinusoidal volume connecting neighbouring PT and (d) at the CV outlet (mean value over the CV outlet); (e–f) magnitude of the velocity projected into a longitudinal cross-section ( $\|\vec{v}_{rz}\|$ ): (e) at PT inlets (longitudinal section through the PT,  $\theta = 0^\circ, 180^\circ$ ) and (f) at the VS inflow into the lobule (longitudinal section through the midpoints of the VS,  $\theta = \pm 90^\circ$ ).

(Figures 3(d) and 4(d),(f)). On leaving the PTs, the flow pathways that go directly from the PT into the sinusoids have lower velocities than those that first enter the VS and also than those leaving the PTs in model M0A (see Figure 3(b)). The streamlines in models M10A and M100A are predominantly radial, and the regions midway between neighbouring PTs are better perfused, leading to a more uniform distribution of blood throughout the tissue than in M0A (Figure 4). This effect is more pronounced for higher circumferential permeability in the VS, i.e. more in M100A than in M10A. Moreover, as shown in Table 2, the volumetric flow rate at the outflow of the lobule ( $Q_{\text{lobule}}$ ) is higher when including VS ( $6.58 \times 10^{-5}$  and  $6.78 \times 10^{-5}$  ml/min for M10A and M100A, respectively) than when neglecting VS ( $6.02 \times 10^{-5}$  ml/min for M0A).

### 3.1.2 Flow in the longitudinal cross-section through opposite PTs ( $\theta = 0^\circ, 180^\circ$ )

Figure 5(b) shows the pressure and streamlines in M0A in a longitudinal plane of cross-section containing the axis of

the lobule and two PTs. The flow follows a diagonally downward pathway, due to the combined effects of the imposed  $z$ -component of the pressure gradient and of the radial pressure gradient. The velocity is high at the inflow (Figure 3(e)), lower midway between the PT and the CV and then higher near the CV outflow.

Similar flow patterns are found in M10A and M100A (Figure 5(d),(f)); however, these models have lower velocities at the PT inflow (Figure 3(e)) and higher velocities at the CV outflow.

### 3.1.3 Flow in the longitudinal cross-section through the centrelines of opposite VS ( $\theta = \pm 90^\circ$ )

Figure 6(b) shows the pressure in M0A in a longitudinal plane of cross-section containing the axis of the lobule and passing through the midpoints of two VS. The pressure decreases from the outer boundary to the CV outflow. Flow velocities in this plane are generally smaller than the velocities in the plane passing through the PTs, especially near the peripheral boundaries, where there is a stagnation

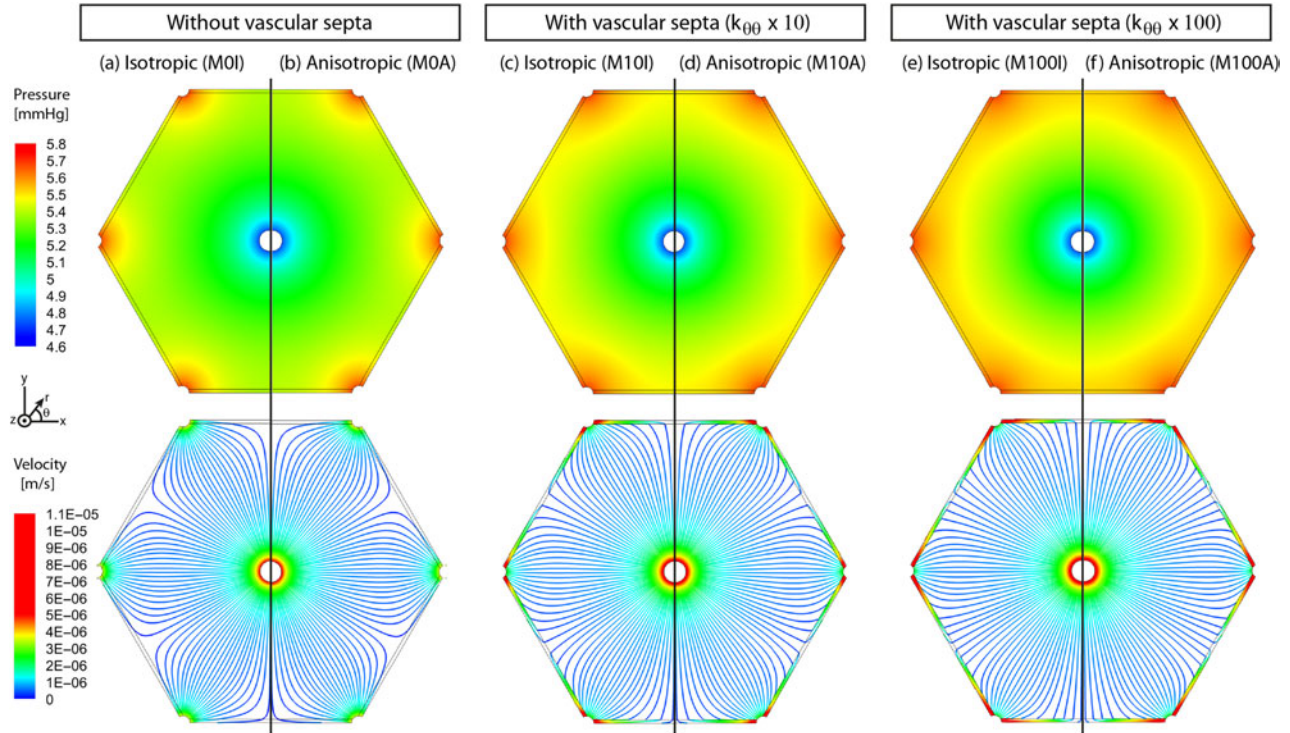

Figure 4. Pressures (top) and streamlines (bottom, coloured according to the magnitude of the projection of the velocity into the plane ( $\|\vec{v}_{r,\theta}\|$ )) obtained on the middle cross-section ( $z = 0$ ) of the lobule models: (a) M0I, (b) M0A, (c) M10I, (d) M10A, (e) M100I and (f) M100A.

line with a zero velocity midway between two PTs along the outer lobule borders.

Comparing the models with and without VS, we find that the pressures in M10A and M100A are generally higher than those in M0A, see Figure 6(b),(d),(f). The planar velocity magnitudes at the VS-lobule interfaces are  $1.40 \times 10^{-6}$  and  $1.43 \times 10^{-6}$  m/s for M10A and M100A, respectively (see Figure 3(f)). However, velocities at the CV outflow are higher.

In the end, the models without VS show low magnitudes of velocity and, thus, poor perfusion of the zones lying between neighbouring PTs (Figures 4(a),(b) and 7(a),(b)). In contrast, the models with VS predict a better perfusion of these zones and a more uniform velocity distribution (Figures 4(c)–(f) and 7(a),(b)). Figure 7(c),(d) shows, respectively, the in-plane and the total (3D) magnitudes of the velocity as a function of the angle on a circle around the CV ( $r = 0.3$  mm) in order to investigate the homogeneity of the perfusion. The flow is more homogeneous when VS are included, with the amplitude of the velocity magnitude fluctuations clearly being smaller when including VS.

### 3.2 Comparison of isotropic versus anisotropic permeability

In this section, we discuss isotropic versus anisotropic conditions, focusing on models M100I and M100A.

In the hexagonal cross-section  $z = 0$ , the pressure contours and directions of the flow trajectories are similar in the isotropic and the anisotropic models (Figure 4(e),(f)). The in-plane magnitudes of the velocity as well as the total flow rate through the lobule are almost equal (slightly higher in the anisotropic cases):  $6.77 \times 10^{-5}$  ml/min in M100I and  $6.78 \times 10^{-6}$  ml/min in M100A (Table 2).

Figures 5(e),(f) and 6(e),(f) show that the flow is similar for the corresponding cases of isotropic and anisotropic permeability, although it is closer to vertical in the anisotropic case. As such, anisotropic permeability leads to a larger longitudinal  $z$ -component of the velocity due to the larger longitudinal permeability in the  $z$ -direction. Similar effects are observed in the other models: M0I, M0A, M10I and M10A.

Figure 7(c) shows that the planar velocity along a circle around the CV in the hexagonal cross-section is approximately equal for both the anisotropic and isotropic cases, with isotropic conditions resulting in only a slightly higher variation of the predicted velocity. However, the spatially averaged magnitude of the total (3D) velocity is significantly higher and also shows a smaller spatial variance in the anisotropic case, owing to the higher  $z$ -component of the velocity (Figure 7(d)).

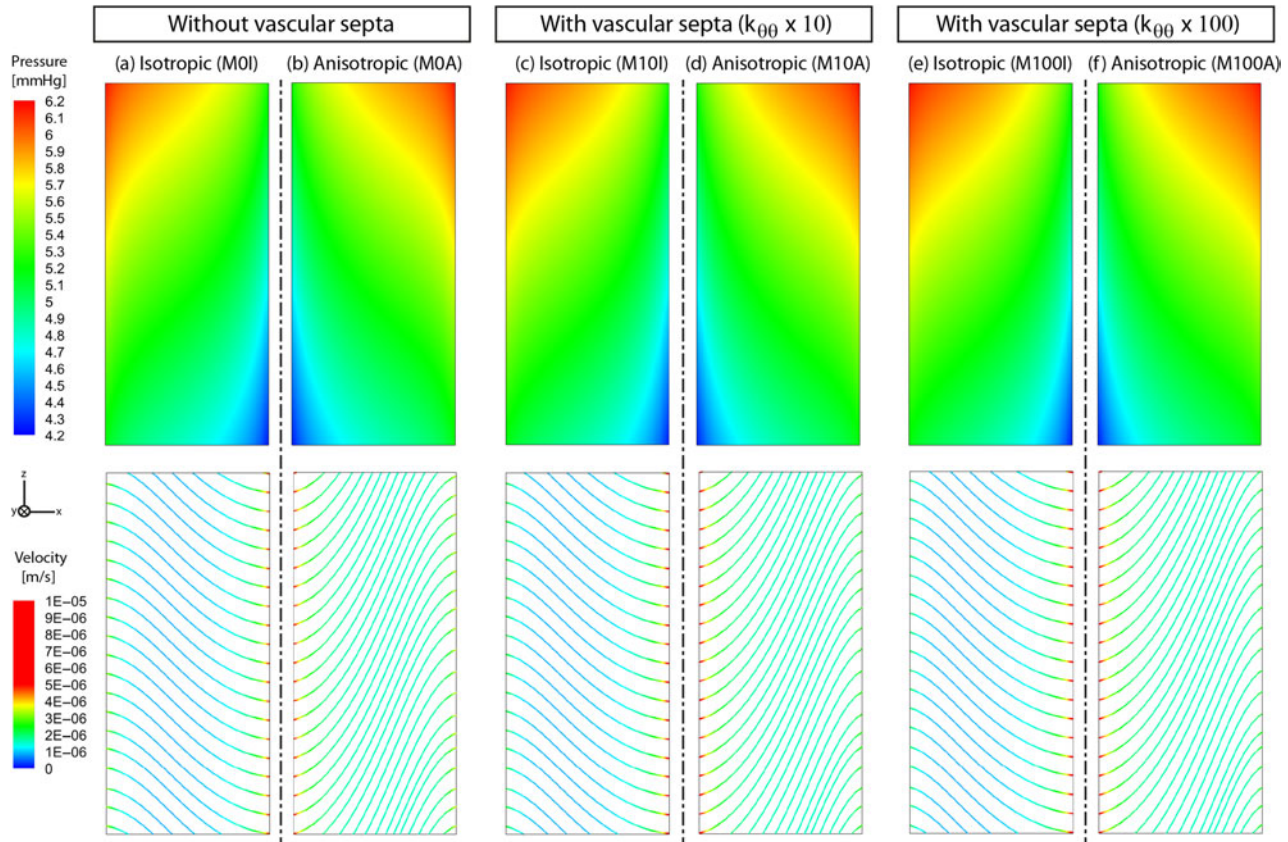

Figure 5. Pressures (top) and streamlines (bottom, coloured according to the magnitude of the projection of the velocity into the plane ( $\|\vec{v}_z\|$ )) obtained on a longitudinal cross-section passing through two PTs ( $\theta = 0^\circ, 180^\circ$ ) of the lobule models: (a) M0I, (b) M0A, (c) M10I, (d) M10A, (e) M100I and (f) M100A.

### 3.3 Parameter sensitivity study

Boundary conditions as well as geometrical features were varied to investigate the sensitivity of the lobule fluid dynamics to the choice of such parameters.

#### 3.3.1 Impact of changes on imposed boundary conditions

Comparison of Figure 5(f) with Figure 8 illustrates how changes in the pressure gradient in the  $z$ -direction affect the solution. Increasing the longitudinal pressure gradient leads, as expected, to a larger  $z$ -component of the velocity. In contrast, the lobule and total liver outflow and resistance do not change in comparison with the baseline model M100A (Tables 1 and 2). Obviously, the radial and circumferential components of the velocity do not depend on the longitudinal pressure gradient, whereas the  $z$ -component of the velocity is directly proportional to  $\partial p / \partial z$ . As the total flux through the lobule only depends on the radial and circumferential velocity components, it is also independent of  $\partial p / \partial z$ .

Second, the PT–CV pressure drop was increased by increasing the PT pressure by 0.5 and 1 mmHg (Figure 9).

This resulted in higher velocities and lobule flows ( $1.03 \times 10^{-4}$  and  $1.39 \times 10^{-4}$  ml/min for a 0.5 and 1 mmHg increase of the PT pressure, respectively), because the flow is given by dividing the pressure difference by the resistance (see also the Appendix for details). The lobule resistance remained equal, since the simulation geometry did not change (Tables 1 and 2). Lobule and total liver flow increases were linearly proportional to the increase in the PT–CV pressure drop (Table 2). Note that this dependence of the results on the PT–CV pressure difference is predictable, owing to the linearity of the governing equations: the radial and circumferential components of the velocity (and consequently also the flux through the lobule) are directly proportional to the PT–CV pressure drop, although such difference does not affect the  $z$ -component of the velocity. Doubling the PT–CV pressure drop, for instance, thus implies doubling the flux through the lobule.

#### 3.3.2 Impact of geometry-related parameter variations

Reducing the VS thickness to  $5 \mu\text{m}$  (instead of  $10 \mu\text{m}$ ) results in a decrease of the fraction of the PT inflow that

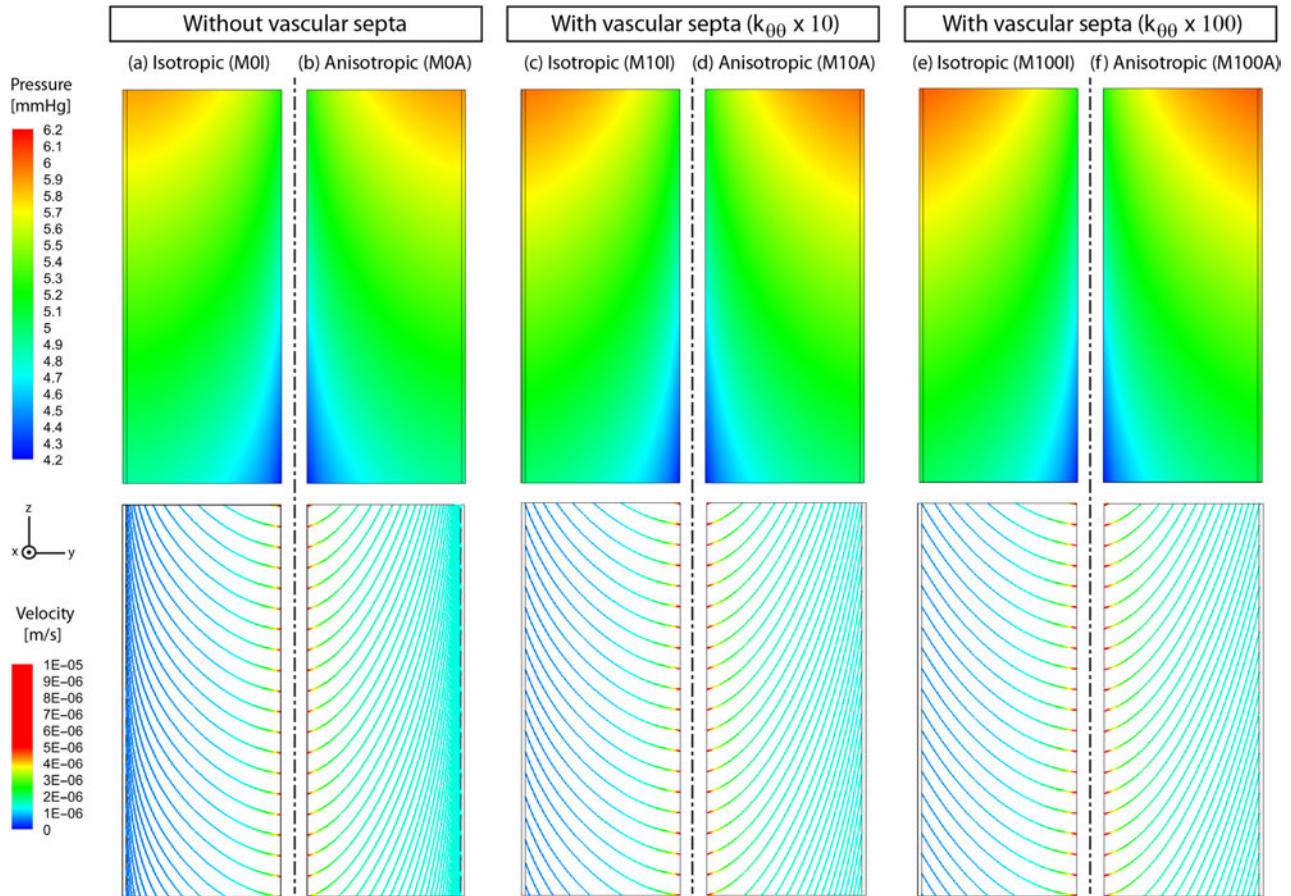

Figure 6. Pressures (top) and streamlines (bottom, coloured according to the magnitude of the projection of the velocity into the plane) obtained on a longitudinal cross-section passing through the centre of two opposite VS ( $\theta = \pm 90^\circ$ ) of the lobule models: (a) M0I, (b) M0A, (c) M10I, (d) M10A, (e) M100I and (f) M100A.

drains into the VS (Figure 10). This led to an increase in the lobule resistance ( $1.46 \times 10^4$  mmHg min/ml) and a decrease in the lobule flow ( $6.51 \times 10^{-5}$  ml/min). As such, decreasing the VS thickness by 50% resulted in a lobule and total liver outflow decrease of 4.0% (Table 2).

Increasing the PT diameter from 40 to 60  $\mu\text{m}$  results in a decrease in the lobule resistance ( $1.35 \times 10^4$  mmHg min/ml). Consequently, the lobule outflow increased ( $7.01 \times 10^{-5}$  ml/min). Pressures and velocities changed accordingly, as illustrated in Figure 10 (lower PT inflow velocity, but a larger PT inflow front and higher CV outflow velocity). A 50% increase of the PT diameter thus resulted in a 3.4% increase of the lobule and total liver outflow (Table 2).

When increasing the CV diameter to 90  $\mu\text{m}$  (instead of 60  $\mu\text{m}$ ; Figure 10), the lobule outflow increases ( $7.80 \times 10^{-5}$  ml/min), while the lobule resistance decreases due to a larger CV outflow front ( $1.22 \times 10^4$  mmHg min/ml). As such, a 50% CV diameter increase results in a 15.1% increase of the lobule and total liver outflow (Table 2).

Furthermore, when reducing the lobule circumferential diameter to 0.5 mm (Figure 10), there is a significant

increase in the lobule flow ( $9.74 \times 10^{-5}$  ml/min), implying that the lobule resistance to flow is smaller ( $9.75 \times 10^3$  mmHg min/ml). In addition, a smaller lobule results in a larger number of lobules in a liver of a given size, and leads, in this case, to a total estimated liver flow of 900 ml/min. Consequently, a 50% decrease of the lobule circumferential diameter leads to a 43.7% increase of the lobule outflow and a 474.8% increase of the total liver outflow (Table 2).

In summary, among the model parameters studied, the lobule circumferential diameter is the most sensitive parameter when looking at the total liver outflow, followed by the pressure drop between the PTs and the CV.

#### 4. Discussion

In this study, a 3D computational fluid dynamics model of a liver lobule was developed to study the hepatic microcirculation in order to investigate the effect of VS and anisotropic permeability properties. Additionally, a parameter sensitivity analysis was carried out to study

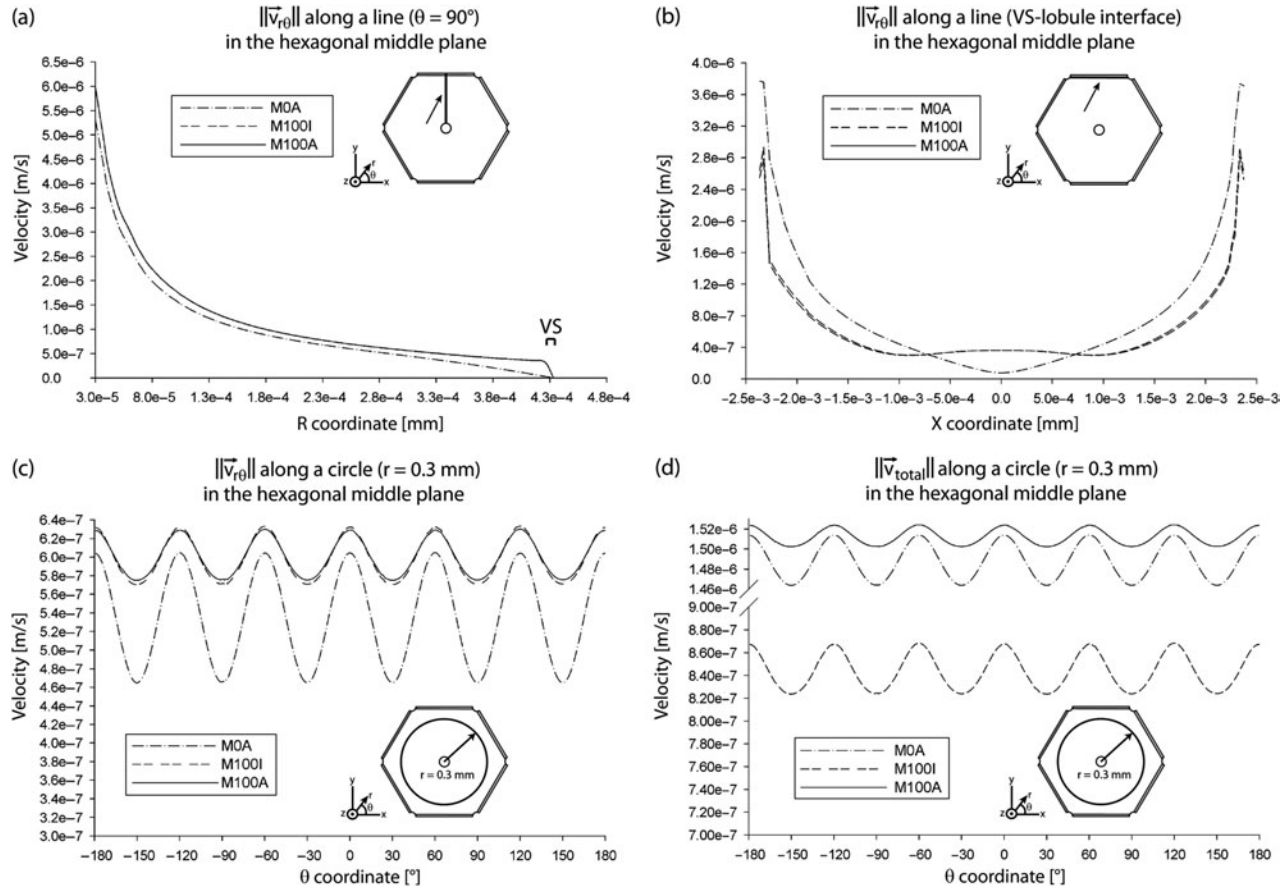

Figure 7. Comparison of the velocities at various locations for models M0A, M100I and M100A. (a–c) Magnitudes of the projection of the velocity in the cross-section ( $\|\vec{v}_{r0}\|$ ): (a) along a line connecting the CV to the middle of a VS ( $\theta = 90^\circ$ ) (the range of  $r$  is  $0.030 \text{ mm} < r < 0.433 \text{ mm}$ ), (b) along a line connecting two PTs and (c) around the circle centred on the CV with radius  $0.3 \text{ mm}$ , plotted against the angle. (d) Magnitudes of the 3D velocity vector around the same circle as shown in (c).

the influence of the choice of geometric and physic parameters on the lobule fluid dynamics.

The models with VS clearly show better perfusion of the zones lying between neighbouring PTs compared with the models without VS, and the flow patterns are more homogeneous when VS are included. The physiological needs of the hepatocytes, and, in particular, the requirement of a sufficient supply of oxygen and nutrients for every cell make the models that include VS seem more physiologically plausible than those without. This is particularly the case for the cells midway between neighbouring PTs, for which the supply of oxygen is dramatically increased by the existence of VS.

Models with anisotropic permeability show a more spatially homogeneous magnitude of the velocity field compared with those having isotropy (Figure 7). Again, this is especially relevant for the relatively poorly perfused zone midway between the neighbouring PTs. However, one has to be cautious with this interpretation, since the influence of anisotropy depends on the applied boundary

conditions, in particular, on the longitudinal pressure gradient. To our knowledge, there is no data available in literature on the longitudinal pressure gradient over a lobule (defined in our model as  $1 \text{ mmHg per mm}$ ; see Section 2.2). Therefore, we carried out a parameter study in which variations of the longitudinal pressure gradient showed, as expected, differences in the  $z$ -components of the velocities, but the lobule and total liver flow did not change (Tables 1 and 2).

In addition, the sensitivity of other parameters was analysed (Tables 1 and 2), showing that the total liver outflow was most sensitive to changes in the lobule cross-sectional size (determined by the lobule circumferential diameter) and the PT–CV pressure drop. In contrast, the total liver outflow was not or only slightly sensitive to some other parameters (such as the longitudinal pressure gradient in the  $z$ -direction and the PT diameter).

Estimations of the flow rate and resistance of both a single lobule and the liver as a whole for M100A resulted in  $Q_{\text{lobule}} = 6.78 \times 10^{-5} \text{ ml/min}$ ,  $Q_{\text{liver}} = 157 \text{ ml/min}$ ,

Table 2. Overview of results for the simulated cases: the lobule and estimated total liver flow ( $Q$ ) and resistance ( $R$ ; see Appendix for details), as well as the percentage of difference of the lobule and total liver outflow relative to the baseline model M100A (calculated as  $(Q_{Mx} - Q_{M100A})/Q_{M100A}$ ).

Model	$Q_{lobule}$ (ml/min)	$Q_{liver}$ (ml/min)	$R_{lobule}$ (mmHg min/ml)	$R_{liver}$ (mmHg min/ml)	Percentual difference of $Q_{lobule}$ (%)	Percentual difference of $Q_{liver}$ (%)

$R_{lobule} = 1.40 \times 10^4$  mmHg min/ml and  $R_{liver} = 6.07 \times 10^{-3}$  mmHg min/ml (Table 2). However, physiological values of  $Q_{liver}$  are around 1500 ml/min, which our baseline model underestimates. This is due to the assumptions that we made in our modelling, which is not surprising as there are significant variations in certain parameters reported in the literature (PT and CV pressures and diameters, lobule dimensions, liver weight, flow rate, etc.). We anticipate that, as better estimates of these parameters become available, the model will become more realistic and can be tuned based on these parameters so that it effectively leads to realistic whole-liver flow characteristics. For example, with a lobule diameter of 0.5 mm and a pressure in the PT of 0.5 or 1 mmHg above the default values, the flow rate through the whole liver is 1380 ml/min (M100A\_10) or 1850 ml/min (M100A\_11), respectively, and these values are within the physiological range (Table 2).

It is important to stress that we did not perform a direct validation of the proposed models, which would require measurements of pressures or flows at the liver microcirculation level, which is very challenging. However, our results correspond to values that have been described in the literature, and we expect the qualitative predictions of our model to be valid. The demonstrated differences in the flow patterns, especially in the presence of VS, are independent of the assumed sets of boundary conditions. As such, our models incorporating VS and anisotropic permeabilities are probably more accurate, as they result in more homogeneous flow patterns compared with the previous models.

When comparing the outcomes of our models with literature, the highest magnitudes of velocity were found near the inflow from the PTs and near the CV, which agrees with the findings of Bonfiglio et al. (2010) and Ricken et al. (2010). Cohen et al. (2011) also stated that the velocity near the CV is higher, resulting in a region of hepatocytes near the CV that have a much higher flux of blood passing through them, as compared with hepatocytes that are located near the periphery. The flow patterns in the longitudinal sections through the PTs, shown in Figure 5, are also similar to those reported earlier by Ricken et al. (2010). However, in their study, the streamlines are closer to those that we obtained in our isotropic models, and they are orientated further from the axis than the streamlines that we obtained in our anisotropic models. This seems to be a logical consequence of the fact that Ricken et al. (2010) used a permeability that is isotropic over the longitudinal cross-section in their 2D model. The flow patterns in the hexagonal cross-sectional plane of the models without VS (shown in Figure 4(a),(b)) are also qualitatively similar to those obtained by Bonfiglio et al. (2010). Furthermore, the results obtained by Siggers et al. (2010) in their dimensionless 2D model including VS were comparable

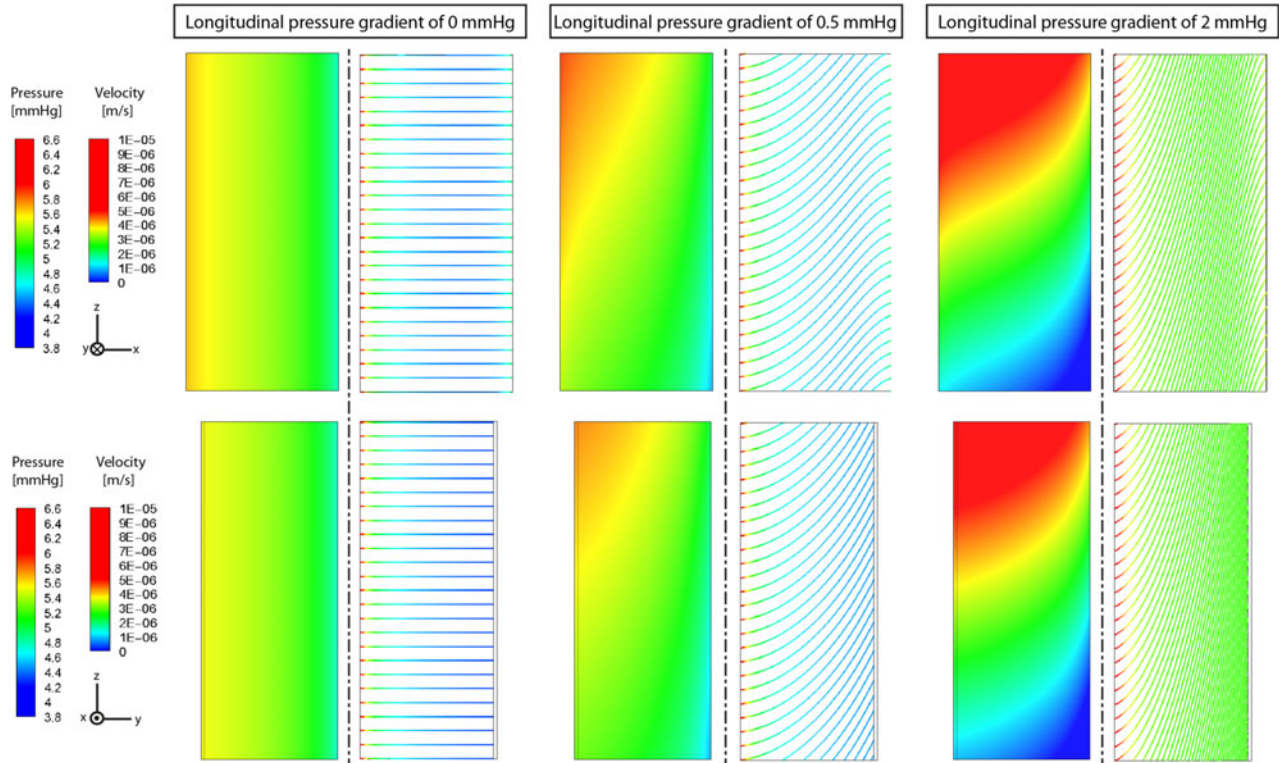

Figure 8. Pressures and streamlines (coloured according to the magnitude of the projection of the velocity into the plane  $\|\vec{v}_{rz}\|$ ) obtained on a longitudinal cross-section passing through two PTs (top;  $\theta = 0^\circ, 180^\circ$ ) and on a longitudinal cross-section passing through the centre of two opposite VS (bottom;  $\theta = \pm 90^\circ$ ) for variations of the pressure gradient along the longitudinal  $z$ -direction (0, 0.5 and 2 mmHg corresponding to models M100A\_1, M100A\_2 and M100A\_3, respectively) compared with the baseline model.

with our models including VS (projection into the hexagonal cross-sectional plane). Note that the 3D lobule model obtained in this study could also be interpreted and solved as a combination of a 2D porous model (Bonfiglio

et al. 2010; Siggers et al. 2010), with a superimposed pressure gradient in the  $z$ -direction and the corresponding  $z$ -component of the velocity as our model uses a prescribed longitudinal pressure drop. Comparing our model with the

Figure 9. Pressures and streamlines (coloured according to the magnitude of the projection of the velocity into the plane  $\|\vec{v}_{r\theta}\|$ ) obtained on the middle cross-section ( $z = 0$ ) using a 0.5 and 1 mmHg increase of the PT pressure (corresponding to models M100A\_4 and M100A\_5, respectively) compared with the baseline model.

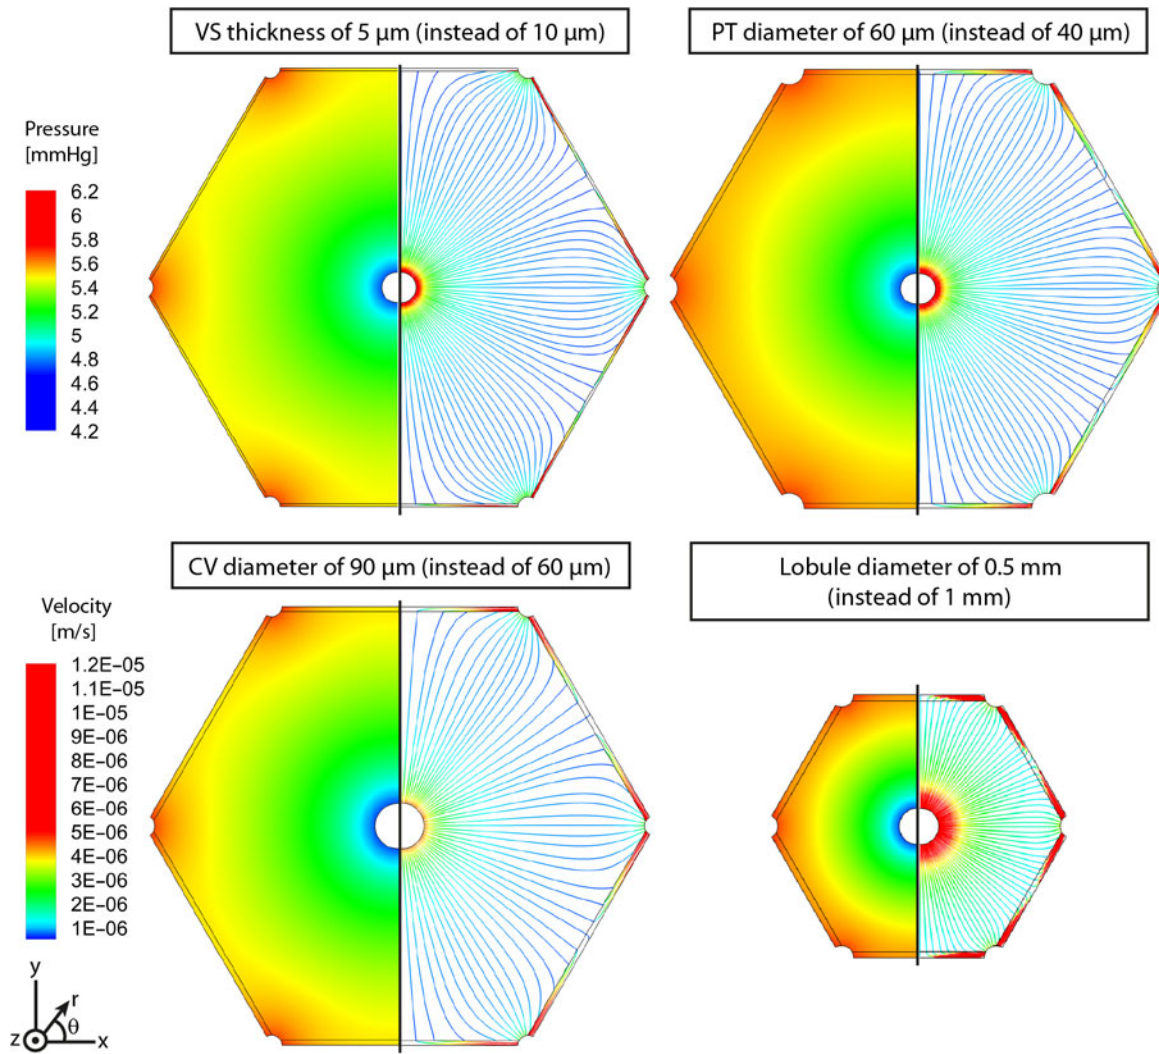

Figure 10. Pressures and streamlines (coloured according to the magnitude of the projection of the velocity into the plane  $\|\vec{v}_{r\theta}\|$ ) obtained on the middle cross-section ( $z = 0$ ) using variations in the geometrical features compared with the baseline model: VS thickness of  $5\ \mu\text{m}$  (M100A\_6), PT diameter of  $60\ \mu\text{m}$  (M100A\_7), CV diameter of  $90\ \mu\text{m}$  (M100A\_8) and a lobule circumferential diameter of  $0.5\ \text{mm}$  (M100A\_9).

3D model of Rani et al. (2006), some major differences exist regarding the modelling approach. Rani et al. (2006) based the fluid domain of their model on the 3D structure of a liver acinus, while in this study, we used the classic schematic hexagonal lobule to represent the functional unit of the liver microcirculation (Figure 1). Which model is most appropriate to represent the functional unit of the liver (e.g. the classic lobule, primary lobule, liver acinus and choleohepaton) is still a matter of debate (Ekataksin and Wake 1991, 1997; Teutsch et al. 1999; Ekataksin 2000; Teutsch 2005; Burt et al. 2007). Furthermore, the model of Rani et al. (2006) included a terminal HA, PV and CV, as well as two sinusoids having a  $23.5\ \mu\text{m}$  radius and fenestrations. These sinusoidal diameter values seem to be high, as sinusoidal diameters are typically reported as being in the order of magnitude of  $10\ \mu\text{m}$  (which we also

observed in a previous study (Debbaut et al. 2012)). Larger sinusoids will result in lower vascular resistances and higher permeability compared with our model geometry. Another difference is that Rani et al. (2006) used non-Newtonian fluid properties, while we modelled blood as an incompressible Newtonian fluid. Non-Newtonian effects (such as the Fahraeus–Lindqvist effect (Barbee and Cokelet 1971) and the shear thinning effect (Rani et al. 2006)) are important on the scale of the microscopic sinusoids. Nevertheless, Bonfiglio et al. (2010) reported pressure differences of less than 4% when comparing the results of a Newtonian model with those of a shear-thinning model. This seems to suggest that non-Newtonian effects are of minor importance for our models. As for the boundary conditions, Rani et al. (2006) applied a pressure drop from 95 to 20 mmHg along the terminal HA and from

25 to 15 mmHg along the terminal PV, which seems quite high (a PV pressure of 15–25 mmHg is considered indicating portal hypertension). Thus, combining higher pressure(s) (drops) with lower vascular resistances (due to higher sinusoidal diameters) leads to significant differences in the order of magnitude of the predicted velocities with our data. Furthermore, the model of Rani et al. (2006) explicitly accounts neither for the effect of more than two tortuous sinusoids nor for the presence of VS.

## 5. Conclusion

In this study, we developed a 3D mathematical model of a liver lobule, using a porous medium approach, incorporating the effect of VS and anisotropic permeability. The inclusion of VS leads to better perfusion of the zones lying between PTs and a more spatially homogeneous perfusion of the lobule. The inclusion of anisotropic permeability results in clearly different flow patterns, with streamlines that are oriented closer to the lobule axes. A parameter study revealed that the lobule and total liver flow is most sensitive to variations of the lobule circumferential diameter and the radial pressure drop. In conclusion, the findings suggest that especially the presence of VS results in a more physiologically realistic model of the hepatic microcirculation and that the model can be tuned to correspond with physiological flows and pressures. Future work should aim at direct validation of the model and to explore applications for a better understanding of liver pathophysiology as well as improved diagnosis and treatment of liver disease.

## Appendix: Estimation of the lobe-specific and total liver flow and resistance

Based on the simulation results, the flow rate in a single lobule,  $Q_{\text{lobule}}$  ( $\text{m}^3/\text{s}$ ), can be estimated by multiplying the surface area of the CV by a typical normal velocity component of the flux entering the CV

$$Q_{\text{lobule}} = \|\vec{v}_{\text{CV}}\| \cdot A_{\text{CV}} = \|\vec{v}_{\text{CV}}\| \cdot 2\pi r_{\text{CV}} \cdot l_{\text{lobule}}, \quad (\text{A1})$$

where  $\vec{v}_{\text{CV}}$  ( $\text{m/s}$ ) is the radial velocity at the CV outflow,  $A_{\text{CV}}$  ( $\text{m}^2$ ) is the surface area of the CV lumen,  $r_{\text{CV}}$  ( $30 \times 10^{-6} \text{ m}$ ) is the CV radius and  $l_{\text{lobule}}$  ( $10^{-3} \text{ m}$ ) is the lobule length. The total liver flow,  $Q_{\text{liver}}$  ( $\text{m}^3/\text{s}$ ), is calculated by multiplying  $Q_{\text{lobule}}$  by the number of lobules,  $n$ , which is estimated by dividing a typical volume of the liver by the volume of a lobule (hexagonal prism volume):

$$Q_{\text{liver}} = Q_{\text{lobule}} \cdot n, \quad (\text{A2})$$

$$n = \frac{V_{\text{liver}}}{V_{\text{lobule}}} = \frac{m_{\text{liver}}/\rho_{\text{liver}}}{3 \cdot r_{\text{lobule}} \cdot \sqrt{3} r_{\text{lobule}}/2 \cdot l_{\text{lobule}}}, \quad (\text{A3})$$

where  $V_{\text{liver}}$  ( $\text{m}^3$ ) is the liver volume,  $V_{\text{lobule}}$  ( $\text{m}^3$ ) is the lobule volume,  $m_{\text{liver}}$  (1.5 kg) is the mass of the liver (Marieb and Hoehn 2008),  $\rho_{\text{liver}}$  ( $10^3 \text{ kg/m}^3$ ; equal to water) is the liver density and  $r_{\text{lobule}}$  is the length of a side of the lobule hexagonal cross-section. The lobule-specific hydraulic resistance,  $R_{\text{lobule}}$  ( $\text{Pa s/m}^3$ ), is estimated by dividing the pressure difference between the inflow and outflow (along the streamlines running from PT to CV) by the lobule-specific flow:

$$R_{\text{lobule}} = \frac{\Delta P_{\text{lobule}}}{Q_{\text{lobule}}}. \quad (\text{A4})$$

Since the lobules are arranged in parallel with respect to the blood flow, the total hydraulic resistance of the microvasculature of the liver is calculated as the lobule resistance divided by the estimated number of lobules  $n$ :

$$R_{\text{liver}} = \frac{R}{n}. \quad (\text{A5})$$
